Email: *shehryar [at] nevada {dot} unr {dot} edu*,
Office Hours: Friday, 11:00 am - 1:00 pm at ARF 116

Athanasia Katsila,

Email: *akatsila [at] nevada {dot} unr {dot} edu*,
Office Hours: Tuesday, 10:30 am - 12:30 pm at SEM 211

Grading Policy Update

The **WebCampus** will be kept open until midnight for late submissions

Late assignments will be penalized by 20% per day, except holidays.

Programming Assignments

- You are responsible for the naming convention on the submitted file *unr-net-id* _a*M*.tar.gz

- where:
  - *unr-net-id* is your UNR Net ID,
  - *M* is the number of the project

- The execution must always be of the form

  tar -cvf *unr-net-id*_a*M*.tar *file1.h file2.h etc.h* **README.txt**

  - gzip *unr-net-id*_a*M*.tar

- README is required!!

- Test your code in any linux machine.

Programming Assignments

In README file:

- `How to compile`
  - `g++ -std=c11` *file1.h file2.h etc.h*

- Clearly state it if your code is not compiling properly.

- Explain which parts of the assignment are incomplete.

- There will be a 30% penalty if any of these are missing.

A Brief Introduction to C++

C++ Interlude 1

We will provide a brief overview of C++

Many of the statements in C++ are very similar to C#(and Java)

– It is assumed you remember these from CS 202

A Brief Introduction to C++

We will see:

- The similarities between C# and C++
- Some differences, including:
  - Global variables and functions
  - The preprocessor, compilation, namespaces
  - Printing
- Concluding with
  - Classes, templates
  - Pointers
  - Memory allocation and deallocation

Control Statements

All control statements are similar

```
    if ( statement ) {
        // ...
    } else if ( statement ) {
        // ...                          while ( statement ) {
    } else {                               // ...
        // ...                           }
    }
                          for ( int i = 0; i < N; ++i ) {
                              // ...
  do {                        }
      // ...
  } while ( statement );
```

Operators

Operators have similar functionality for built-in datatypes:

- Assignment   `=`
- Arithmetic   `+`   `-`   `*`   `/`   `%`

                           `+=`   `-=`   `*=`   `/=`   `%=`

- Autoincrement   `++`
- Autodecrement   `--`
- Logical   `&&`   `||`   `!`
- Relational   `==`   `!=`   `<`   `<=`   `>=`   `>`
- Comments   `/*`   `*/`

                           `// to end of line`

- Bitwise   `&`   `|`   `^`   `~`

                           `&=`   `|=`   `^=`

- Bit shifting   `<<`   `>>`

                           `<<=`   `>>=`

Accessing arrays is similar:

```
const int ARRAY_CAPACITY = 10; // prevents reassignment
int array[ARRAY_CAPACITY];

array[0] = 1;
for ( int i = 1; i < ARRAY_CAPACITY; ++i ) {
    array[i] = 2*array[i – 1] + 1;
}
```

Recall that arrays go from

0 to **ARRAY_CAPACITY – 1**

Definition:
The *capacity* of an array is the entries it can hold
The *size* of an array is the number of useful entries

Functions

Function calls are similar, however, they are not required to be part of a class:

```cpp
#include <iostream>
using namespace std;

// A function with a global name
int sqr( int n ) {
    return n*n;
}

int main() {
    cout << "The square of 3 is " << sqr(3) << endl;
    return 0;
}
```

C++/C# Differences

We will look at categories of differences between C++ and C#:

- Including header files (the preprocessor)
- The file is the base of compilation
- Namespaces
- Printing

C++ is based on C, which was written in the early 1970s

Any command starting with a **#** in the first column is not a C/C++ statement, but rather a preprocessor statement

- The preprocessor performed very basic text-based (or *lexical*) substitutions
- The output is sent to the compiler

The sequence is:

file (`filename.cpp`) → preprocessor → compiler (g++)

Note, this is done automatically by the compiler: no additional steps are necessary

At the top of any C++ program, you will see one or more directives starting with a **#**, *e.g.*,

```
#include <iostream>
```

iostream.h   intro.cpp

```cpp
#include<iostream>
using namespace std;

int sqr( int n ) {
    return n*n;
}

int main() {
    cout << "The square of 3 is " << sqr(3) << endl;
    return 0;
}
```

preprocessor

to the compiler

You will write your code in a file such as `Single_list.h` where you will implement a data structure

This file will be included in our tester file `Single_list_tester.h` with a statement such as:

    #include "Single_list.h"

The file `Single_list_driver.cpp` then includes the tester file:

    #include "Single_list_tester.h"

You will note the difference:

```
#include <iostream>

#include "Single_list.h"
```

The first looks for a file `iostream.h` which is shipped with the compiler (the standard library)

The second looks in the current directory

Libraries

In CS 302, you are free to put all code in the header file

This is not normal practice:

- Usually the header (`.h`) file only contains declarations
- The definitions (the actual implementations) are stored in a related file and compiled into an object file

The C++ Preprocessor

mylib.h

```
#ifndef _MYLIB_H
#define _MYLIB_H

int sqr( int n );

int cube( int n );

int sumi( int n );

int sumi2( int n );

int factorial( int n );

#endif
```

mylib.cpp

```
#include "mylib.h"

int sqr( int n ) {
    return n*n;
}

int cube( int n ) {
    return n*n*n;
}

int sumi( int n ) {
    return (n*(n + 1))/2;
}

int sumi2( int n ) {
    return (n*(n + 1)*(2*n + 1))/6;
}

int factorial( int n ) {
    if ( n <= 1 ) {
        return 1;
    } else {
        return n*factorial(n - 1);
    }
}
```

mylib.h

```
#ifndef _MYLIB_H
#define _MYLIB_H

int sqr( int n ) {
    return n*n;
}

int cube( int n ) {
    return n*n*n;
}

int sumi( int n ) {
    return (n*(n + 1))/2;
}

int sumi2( int n ) {
    return (n*(n + 1)*(2*n + 1))/6;
}

int factorial( int n ) {
    if ( n <= 1 ) {
        return 1;
    } else {
        return n*factorial(n - 1);
    }
}

#endif
```

compiled into a library

included in source file

mylib.o
mylib.so

only the source code is compiled

included in source file

everything is compiled

linked with library to generate the executable file

executable is generated (no linking necessary)

The C++ Preprocessor

With all these includes, it is always necessary to avoid the same file being included twice, otherwise you have duplicate definitions

This is done with guard statements:

```
#ifndef SINGLE_LIST_H
#define SINGLE_LIST_H

template <typename Type>
class Single_list {
  ///...
};
#endif
```

The C++ Preprocessor

This class definition contains only the signatures (or *prototypes*) of the operations

The actual member function definitions may be defined elsewhere, either in:

- The same file, or
- Another file which is compiled into an object file

In C#, the class is the basis of compiling executable code:

```
class TestProgram {
    public static void Main() {
        System.Console.WriteLine( "Hello World" );
    }
}
```

The existence of a function with the signature

```
public static void Main();
```

determines whether or not a class can be compiled into an executable

In C/C++, the file is the base unit of compilation:

- Any `.cpp` file may be compiled into object code
- Only files containing an `int main()` function can be compiled into an executable

The signature of main is:

```
int main () {
    // does some stuff
    return 0;
}
```

The operating system is expecting a return value

- Usually 0

This file (`example.cpp`) contains two functions

```cpp
#include<iostream>
using namespace std;

int sqr( int n ) {        // Function declaration and
  definition
    return n*n;
}

int main() {
    cout << "The square of 3 is " << sqr(3) << endl;
    return 0;
}
```

To compile this file, we execute on the command line:

```
{ecelinux:1} g++ example.cpp
{ecelinux:2} ls
a.out          example.cpp
{ecelinux:3} ./a.out
The square of 3 is 9
{ecelinux:4}
```

This is an alternate form:

```cpp
#include<iostream>
using namespace std;

int sqr( int );                     // Function declaration

int main() {
    cout << "The square of 3 is " << sqr(3) << endl;
    return 0;
}

int sqr( int n ) {                  // Function definition
    return n*n;                     // The definition can be in another file
}
```

Variables defined:

- In functions are *local variables*
- In classes are *member variables*
- Elsewhere are *global variables*

Functions defined:

- In classes are *member functions*
- Elsewhere are *global functions*

In all these cases, the keyword `static` can modify the scope

Namespaces

Global variables/variables cause problems, especially in large projects

- Hundreds of employees
- Dozens of projects
- Everyone wanting a function `init()`

In C++ (and XML), this is solved using namespaces

A namespace adds an extra disambiguation between similar names

```
namespace unr_mcanbaz{
    int n = 4;
    double mean = 2.34567;

    void init() {
        // Does something...
    }
}
```

There are two means of accessing these global variables and functions outside of this namespace:
- The namespace as a prefix: `unr_mcanbaz::init()`
- The `using` statement:

```
using namespace unr_mcanbaz;
```

Namespaces

You will only need this for the standard name space

- – All variables and functions in the standard library are in the **std** namespace

```
#include <iostream>
std::cout << "Hello world!" << std::endl;
```

```
#include <iostream>
using namespace std;          // never used in production code

cout << "Hello world!" << endl;
```

Printing in C++ is done through overloading the **<<** operator:

```
cout << 3;
```

If the left-hand argument of **<<** is an object of type **ostream** (*o*utput *stream*) and the right-hand argument is a **double**, **int**, **string**, etc., an appropriate function which prints the object is called

The format is suggestive of what is happening:

- The objects are being *sent* to the **cout** (*console output*) object to be printed

```
cout << "The square of 3 is " << sqr(3) << endl;
```

The objects being printed are:

- a **string**

- an **int**

- a platform-independent end-of-line identifier

How does

```
cout << "The square of 3 is " << sqr(3) << endl;
```

work?

This is equivalent to

```
((cout << "The square of 3 is ") << sqr(3)) << endl;
```

where **<<** is an operation (like **+**) which prints the object and returns the **cout** object

Visually:

```
((cout << "The square of 3 is ") << sqr(3)) << endl;
```

print `"The square of 3 is "` and return `cout`

```
(                cout                << sqr(3)) << endl;
```

print the result of `sqr(3)` and return `cout`

```
                              cout                << endl;
```

print an end-of-line character (and return `cout`)

```
cout;
```

Another way to look at this is that

```
cout << "The square of 3 is " << sqr(3) << endl;
```

is the same as:

```
operator<<( operator<<( operator<<( cout, "The square of 3 is " ), sqr(3) ), endl );
```

This is how C++ treats these anyway...

The next five topics in C++ will be:

- Classes
- Templates
- Pointers
- Memory allocation
- Operator overloading

To begin, we will create a complex number class

To describe this class, we could use the following words:

- Store the real and imaginary components
- Allow the user to:
  - Create a complex number
  - Retrieve the real and imaginary parts
  - Find the absolute value and the exponential value
  - Normalize a non-zero complex number

Instead, another way to summarize the properties of a class is through UML Class Diagrams

UML, the Unified Modeling Language is a collection of *best practices* used in designing/modeling (among other things) software systems

The Class Diagram for what we describe may be shown as the following box:

Complex
−re:Real
−im:Real
+create(in r:Real = 0, in i:Real = 0):Complex
+real():Real
+imag():Real
+abs():Real
+exp():Complex
+normalize()
+destroy()

UML Class Diagrams

The three components include:

– the name, the attributes, and the operations

Class Name

Complex
−re:Real   Attributes (class members)   −im:Real
+create(in r:Real = 0, in i:Real = 0):Complex   +real():Real   +imag():Real   Operations   +abs():Real   (member functions,   +exp():Complex   methods, behaviours)   +normalize()   +destroy()
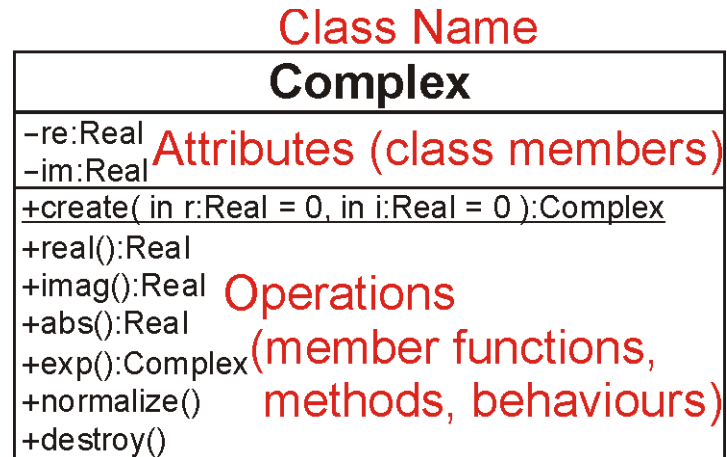

The attributes are described by:

– a visibility modifier, a name, and a type

name   type

private

Complex

–re:Real
–im:Real

+create(in r:Real = 0, in i:Real = 0):Complex
+real():Real
+imag():Real
+abs():Real
+exp():Complex
+normalize()
+destroy()
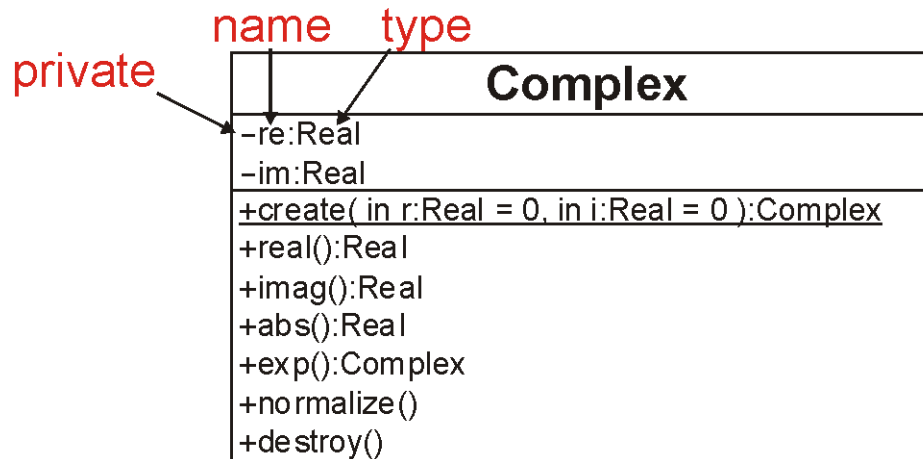

The operations (a.k.a. functions) include:

– a visibility modifier, a name, parameters (possibly with default values) and return val

parameters and types

default values

Complex

−re:Real
−im:Real

name

public

+create(in r:Real = 0, in i:Real = 0):Complex
+real():Real
+imag():Real
+abs():Real
+exp():Complex
+normalize()
+destroy()

return type
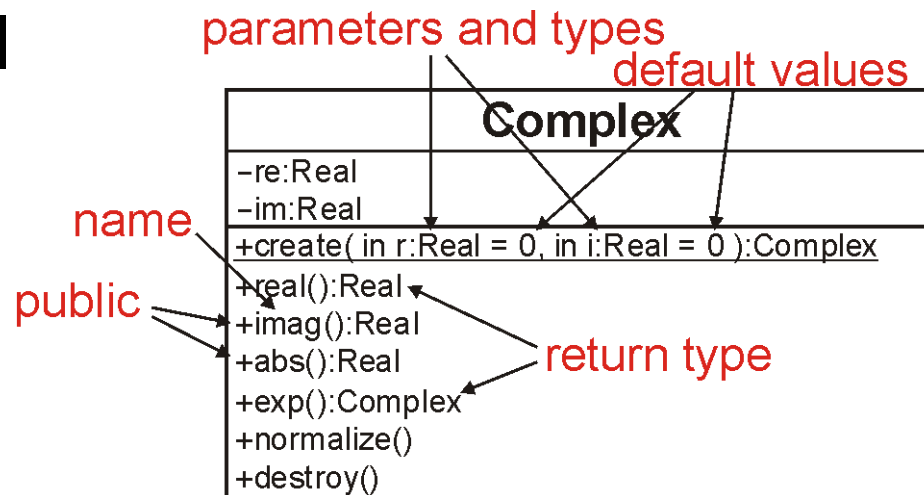

Classes

An example of a C++ class declaration is:

```cpp
class Complex {
    private:
        double re, im;

    public:
        Complex( double = 0.0, double = 0.0 );

        double real() const;
        double imag() const;
        double abs() const;
        Complex exp() const;

        void normalize();
};
```

This only declares the class structure
  – It does not provide an implementation

We could, like C#, include the implementation in the class declaration, however, this is not, for numerous reasons, standard practice

The next slide gives both the declaration of the `Complex` class as well as the associated definitions

- The assumption is that this is within a single file

```
#ifndef _COMPLEX_H
#define _COMPLEX_H
#include <cmath>
class Complex {
    private:
        double re, im;

    public:
        Complex( double = 0.0, double = 0.0 );

        // Accessors
        double real() const;
        double imag() const;
        double abs() const;
        Complex exp() const;

        // Mutators
        void normalize();
};
```

The Complex Class

```
// Constructor
Complex::Complex( double r, double i ):
re( r ),
im( i ) {
    // empty constructor
}
```

Associates functions back to the class

Each member variable should be assigned

The order must be the same as the order in which the member variables are defined in the class

For built-in datatypes, this is a simple assignment. For member variables that are objects, this is a call to a constructor.

For built-in datatypes, the above is equivalent to:
```
// Constructor
Complex::Complex( double r, double i ):re( 0 ), im( 0 ) {
    re = r;
    im = i;
}
```

```cpp
// return the real component
double Complex::real() const {
    return re;
}

// return the imaginary component
double Complex::imag() const {
    return im;
}

// return the absolute value
double Complex::abs() const {
    return std::sqrt( re*re + im*im );
}
```

Refers to the member variables re and im of this class

```cpp
// Return the exponential of the complex value
Complex Complex::exp() const {
    double exp_re = std::exp( re );

    return Complex( exp_re*std::cos(im), exp_re*std::sin(im) );
}
```

```
// Normalize the complex number (giving it unit absolute value, |z| = 1)
void Complex::normalize() {
    if ( re == 0 && im == 0 ) {
        return;
    }

    double absval = abs();
    re /= absval;
    im /= absval;
}

#endif
```

This calls the member function `double abs() const` from the `Complex` class on the object on which `void normalize()` was called

Visibility in C# and Java is described by placing public/private/protected in front of each class member or member function

In C++, this is described by a block prefixed by one of

```
private:
protected:
public:
```

```
class Complex {
    private:
        double re, im;

    public:
        Complex( double, double );

        double real() const;
        double imag() const;
        double abs() const;
        Complex exp() const;

        void normalize();
};
```

The reason for the change in Java/C# was that the C++ version has been noted to be a source of errors

Code could be cut-and-paste from one location to another, and a poorly placed paste could change the visibility of some code:

```
public → private   automatically caught
private → public   difficult to catch and dangerous
```

It is possible for a class to indicate that another class is allowed to access its **private** members

If class `ClassX` declares class `ClassY` to be a friend, then class `ClassY` can access (and modify) the private members of `ClassX`

Visibility

```cpp
class ClassY;                     // declare that ClassY is a class

class ClassX {
    private:
        int privy;                // the variable privy is private

        friend class ClassY;      // ClassY is a "friend" of ClassX
};

class ClassY {                    // define ClassY
    private:
        ClassX value;             // Y stores one instance of X
    public:
        void set_x() {
            value.privy = 42;     // a member function of ClassY can
        }                         // access and modify the private
};                                // member privy of "value"
```

Accessors and Mutators

We can classify member functions into two categories:
- Those leaving the object unchanged
- Those modifying the member variables of the object

Respectively, these are referred to as:
- **Accessors:** we are accessing and using the class members
- **Mutators:** we are changing—mutating—the class members

Good programming practice is to enforce that a routine specified to be an accessor cannot be accidentally changed to a mutator

This is done with the const keyword after the parameter list

```
double abs() const;
```

If a junior programmer were to try change

```
double Complex::abs() const {

  return std::sqrt( re*re + im*im );

}
```
to
```
double Complex::abs() const {

    re = 1.0;                 // modifying
  (mutating) 're'

    return std::sqrt( re*re + im*im );

}
```

the compiler would signal an error

As an example from a previous project, a student did this:

```
template <typename Type>
int Double_sentinel_list<Type>::count( Type const &obj ) const {
    for ( Double_node<Type> *temp = head(); temp != nullptr; temp =
    temp->next() ) {
            if ( temp->retrieve() == obj ) {
                    ++list_size;
            }
    }

    return list_size;
}
```

Here, `list_size` was a member variable of the class

– This code did not compile: the compiler issued a warning that a
  member variable was being modified in a read-only member function

What the student wanted was a local variable:

```
template <typename Type>
int Double_sentinel_list<Type>::count( Type const &obj ) const {
    int obj_count = 0;

    for ( Double_node<Type> *temp = head(); temp != nullptr; temp =
   temp->next() ) {
        if ( temp->retrieve() == obj ) {
            ++obj_count;
        }
    }

    return obj_count;
}
```

Now that we have seen an introduction to classes, the next generalization is templates

In C#, you will recall that all classes descend from the **Object** class

Thus, it is possible to create an array which can hold instances of any class:

```
Object [] array = new Object[10];
```

Suppose you want to build a general linked list which could hold anything

– In C#, you could have it store instance of the class `Object`

Because there is no ultimate `Object` class, to avoid re-implementing each class for each class we are interested in storing, we must have a different mechanism

This mechanism uses a tool called templates

- A function has parameters which are of a specific type
- A template is like a function, however, the parameters themselves are types

That mechanism is called a template:

```
template <typename Type>
Type sqr( Type x ) {
    return x*x;
}
```

This creates a function which returns something of the same type as the argument

To tell the compiler what that type is, we must suffix the function:

```
int n = sqr<int>( 3 );
double x = sqr<double>( 3.141592653589793 );
```

Usually, the compiler can determine the appropriate template without it being explicitly stated

Example:

```cpp
#include<iostream>
using namespace std;

template <typename Type>
Type sqr( Type x ) {
    return x*x;
}

int main() {
    cout << "3 squared is " << sqr<int>( 3 ) << endl;
    cout << "Pi squared is " << sqr<double>( 3.141592653589793 ) << endl;

    return 0;
}
```

Output:
```
3 squared is 9
Pi squared is 9.8696
```

Thus, calling `sqr<int>( 3 )` is equivalent to calling a function defined as:

```
int sqr( int x ) {
    return x*x;
}
```

```
template <typename Type>
Type sqr( Type x ) {
    return x*x;
}
```

The compiler replaces the symbol **Type** with **int**

Templates

Our complex number class uses double-precision floating-point numbers

What if we don't require the precision and want to save memory with floating-point numbers
- Do we write the entire class twice?
- How about templates?

```cpp
#ifndef _COMPLEX_H
#define _COMPLEX_H
#include <cmath>
template <typename Type>
class Complex {
    private:
        Type re, im;

    public:
        Complex( Type const & = Type(), Type const & = Type() );

        // Accessors
        Type real() const;
        Type imag() const;
        Type abs() const;
        Complex exp() const;

        // Mutators
        void normalize();
};
```

The modifier `template <typename Type>` applies only to the following statement, so each time we define a function, we must restate that Type is a templated symbol:

```
// Constructor
template <typename Type>
Complex<Type>::Complex( Type const &r, Type const &i ):re(r), im(i) {
    // empty constructor
}
```

Templates

```cpp
// return the real component
template <typename Type>
Type Complex<Type>::real() const {
    return re;
}

// return the imaginary component
template <typename Type>
Type Complex<Type>::imag() const {
    return im;
}

// return the absolute value
template <typename Type>
Type Complex<Type>::abs() const {
    return std::sqrt( re*re + im*im );
}
```

Templates

```cpp
// Return the exponential of the complex value
template <typename Type>
Complex<Type> Complex<Type>::exp() const {
    Type exp_re = std::exp( re );

    return Complex<Type>( exp_re*std::cos(im), exp_re*std::sin(im) );
}

// Normalize the complex number (giving it unit norm, |z| = 1)
template <typename Type>
void Complex<Type>:noramlize() {
    if ( re == 0 && im == 0 ) {
        return;
    }

    Type absval = abs();
    re /= absval;
    im /= absval;
}

#endif
```

Templates

Example:

```cpp
#include <iostream>
#include "Complex.h"
using namespace std;

int main() {
    Complex<double> z( 3.7, 4.2 );
    Complex<float>  w( 3.7, 4.2 );
    cout.precision( 20 ); // Print up to 20 digits

    cout << "|z| = " << z.abs() << endl;
    cout << "|w| = " << w.abs() << endl;

    z.normalize();
    w.normalize();

    cout << "After normalization, |z| = " << z.abs() << endl;
    cout << "After normalization, |w| = " << w.abs() << endl;

    return 0;
}
```

```
Ouptut:
    |z| = 5.5973207876626123181
    |w| = 5.597320556640625
    After normalization, |z| =
    1.0000000412736744781
    After normalization, |w| = 1
```

One of the simplest ideas in C, but one which most students have a problem with is a pointer

- Every variable (barring optimization) is stored somewhere in
- That address can't we store an addre

MAN, I SUCK AT THIS GAME.
CAN YOU GIVE ME
A FEW POINTERS?

0x3A28213A
0x6339392C,
0x7363682E.

I HATE YOU.

http://xkcd.com/138/

We could simply have an 'address' type:

```
address ptr;     // store an address
                 // THIS IS WRONG
```

however, the compiler does not know what it is an address of (is it the address of an int, a double, etc.)

Instead, we have to indicate what it is pointing to:

```
int *ptr;    // a pointer to an integer
             // the address of the integer variable 'ptr'
```

First we must get the address of a variable

This is done with the **&** operator (**a**mpersand/**a**ddress of)

For example,

```
int m = 5;      // m is an int storing 5
int *ptr;       // a pointer to an int
ptr = &m;       // assign to ptr the
                // address of m
```

Pointers

We can even print the addresses:

```
int m = 5;      // m is an int storing 5
int *ptr;       // a pointer to an int
ptr = &m;       // assign to ptr the
                // address of m
cout << ptr << endl;
```

prints `0xffffd352`, a 32-bit number
  – The computer uses 32-bit addresses

We have pointers: we would now like to manipulate what is stored at that address

We can access/modify what is stored at that memory location by using the * operator (dereference)

```
int m = 5;
int *ptr;
ptr = &m;
cout << *ptr << endl;  // prints 5
```

Similarly, we can modify values stored at an address:

```
int m = 5;
int *ptr;
ptr = &m;

*ptr = 3;      // store 3 at that memory location
cout << m << endl;   // prints 3
```

OKAY, HUMAN.

HUH?

BEFORE YOU HIT "COMPILE", LISTEN UP.

YOU KNOW WHEN YOU'RE FALLING ASLEEP, AND YOU IMAGINE YOURSELF WALKING OR SOMETHING,

AND SUDDENLY YOU MISSTEP, STUMBLE, AND JOLT AWAKE?

YEAH!

WELL, THAT'S WHAT A SEGFAULT FEELS LIKE.

DOUBLE-CHECK YOUR DAMN POINTERS, OKAY?

Pointers to objects must, similarly be dereferenced:

```
Complex z( 3, 4 );
Complex *pz;
pz = &z;
cout << z.abs() << endl;
cout << (*pz).abs() << endl;
```

One short hand for this is to replace

```
(*pz).abs();
```

with

```
pz->abs();
```

Memory Allocation

Memory allocation in C++ and C# is done through the **new** operator

This is an explicit request to the operating system for memory

– This is a very expensive operation

– The OS must:

- Find the appropriate amount of memory,
- Indicate that it has been allocated, and
- Return the address of the first memory location

Memory deallocation differs, however:

– C# uses automatic garbage collection
– C++ requires the user to explicitly deallocate memory

Note however, that:

– *managed C++* has garbage collection
– other tools are also available for C++ to perform automatic garbage collection

Inside a function, memory allocation of declared variables is dealt with by the compiler

```
int my_func() {
    Complex<double> z(3, 4);  // calls constructor with 3, 4
                              // creates 3 + 4 + extras
                      // 16 bytes are allocated by the compiler

    double r = z.abs(); // 8 bytes are allocated by the compiler

    return 0;              // The compiler reclaims the 24 bytes
}
```

Memory for a single instance of a class (one object) is allocated using the new operator, *e.g.*,

```
Complex<double> *pz = new Complex<double>( 3, 4 );
```

The new operator returns the address of the first byte of the memory allocated

We can even print the address to the screen

If we were to execute

```
cout << "The address pz is " << pz << endl;
```

we would see output like:

```
The address pz is 0x00ef3b40
```

Next, to deallocate the memory (once we're finished with it) we must explicitly tell the operating system using the delete operator:

```
delete pz;
```

Memory Allocation

Consider a linked list where each node is allocated:

```
new Node<Type>( obj )
```

Such a call will be made each time a new element is added to the linked list

For each `new`, there must be a corresponding `delete`:
- Each removal of an object requires a call to `delete`
- If a non-empty list is itself being deleted, the destructor must call `delete` on all remaining nodes

To summarize:

– we have seen some of the similarities and differences between C# and C++

– these slides touch on all of the topics which you will need to know to implement all of your assignments

A Quick Introduction to C++

If you have forgotten (or did not learn) what you should have covered in CS 202, there is a full C++ tutorial on the CS 302 web site starting from scratch

The tutorial does not even assume you know what a variable is

There are exercises and example code which you can run yourself
